The Fricke gel dosimeter, based on ferrous sulfate in a hydrogel, enables 3D mapping of radiation dose by oxidizing  $\text{Fe}^{2+}$  to  $\text{Fe}^{3+}$  upon irradiation. This study explored how Fricke yield,  $G(\text{Fe}^{3+})$ , changes with viscosity and radiation type. Using the Monte Carlo track chemistry code IONLYS-IRT, simulations were conducted with protons of 300 MeV (low LET,  $\sim 0.3$  keV/ $\mu\text{m}$ ) and 1 MeV (high LET,  $\sim 25$  keV/ $\mu\text{m}$ ). Diffusion coefficients of radiolytic species, including  $\text{Fe}^{2+}$  and  $\text{Fe}^{3+}$ , were systematically adjusted to represent gels of varying viscosities. Results showed that increasing viscosity restricts  $\text{Fe}^{3+}$  diffusion, enhancing spatial stability but lowering  $G(\text{Fe}^{3+})$ , which reduces dosimeter sensitivity, especially under high-LET radiation. Additional simulations with reduced sulfuric acid concentration (0.05 M vs. 0.4 M) revealed that  $G(\text{Fe}^{3+})$  values converge at  $\sim 100$  s regardless of LET. Overall, the findings demonstrate the usefulness of Monte Carlo modeling in optimizing Fricke gels to balance accuracy, sensitivity, and spatial dose distribution integrity.
